Abstract

Bug prediction is aimed at identifying software artifacts that are more likely to be defective in the future. Most approaches defined so far target the prediction of bugs at class/file level. Nevertheless, past research has provided evidence that this granularity is too coarse-grained for its use in practice. As a consequence, researchers have started proposing defect prediction models targeting a finer granularity (particularly method-level granularity), providing promising evidence that it is possible to operate at this level. Particularly, models mixing product and process metrics provided the best results.

We present a study in which we first replicate previous research on method-level bug-prediction, by using different systems and timespans. Afterwards, based on the limitations of existing research, we (1) re-evaluate method-level bug prediction models more realistically and (2) analyze whether alternative features based on textual aspects, code smells, and developer-related factors can be exploited to improve method-level bug prediction abilities. Key results of our study include that (1) the performance of the previously proposed models, tested using the same strategy but on different systems/timespans, is confirmed; but, (2) when evaluated with a more practical strategy, all the models show a dramatic drop in performance, with results close to that of a random classifier. Finally, we find that (3) the contribution of alternative features within such models is limited and unable to improve the prediction capabilities significantly. As a consequence, our replication and negative results indicate that method-level bug prediction is still an open challenge.

Keywords: Defect Prediction, Empirical Software Engineering, Mining Software Repositories

1. Introduction

The necessary evolution of software systems often leads to the introduction of defects, which possibly preclude the correct functioning of a piece of software and reduce its overall reliability [67]. To tackle this problem, researchers have been developing several techniques to support developers (e.g., verification and testing [17]): one of the most investigated areas is bug-prediction [50], which consists in detecting the areas of a software more likely to contain bugs in the future. Researchers have proposed and evaluated a variety of bug prediction models based on product [5, 74, 73], process [104, 93, 79], socio-technical [102, 13], and developer-related [37, 24] metrics. These models have been evaluated both in within-project scenarios and in cross-project ones [105, 122, 127], with several approaches achieving remarkable prediction performance [33]. Nevertheless, the practical relevance of bug prediction research has been put into question by studies that suggest that bug prediction does not address any real need of developers [109, 68, 66]. One of the main criticisms regards the granularity at which bugs are found [109]. In fact, most of the presented models predict bugs in modules or files — a granularity that is deemed not informative enough for practitioners, because files and modules can be arbitrarily large and inspecting them can require too much work [46]. In addition, considering that larger classes tend to be more bug-prone [62, 87], the effort required to identify the defective part in these classes is even more pronounced [5, 48, 84, 99].

To tackle this limitation, Menzies et al. [74] and Tous et al. [120] conducted the first investigations on a finer granularity, i.e., function-level. Successively, Hata et al. [54] applied this idea to the context of object-oriented systems, proposing a method-level prediction model built using a set of historical metrics and that reported promising performance. Giger et al. [46] went even further and investigated the value of both product and process metrics for method-level prediction model. Specifically, Giger et al. devised three prediction models based on the combination of the two sets of features and evaluated how well they could classify which methods would have at least a bug (binary classification) within a specified time frame. They considered single snapshots of 21 open source software (OSS) projects in Java and reported promising results: 84% precision and 88% recall.

In this paper, we present a work that continues on this line of research.1 First, we replicate the investigation conducted by Giger et al. [46] on bug prediction at

method-level. We use the same features and classifiers as the reference work, but on a different dataset to test the generalizability of their findings. While our results show similar performance as the reference work, we observed two key limitations that may possibly bias the interpretation of the achieved findings. On the one hand, Giger et al. [46] took the change history and predicted bugs from the same time frame (which could lead to incorrect results) and used cross-validation (which have been reported as at the risk of producing biased estimates in certain circumstances [118]). On the other hand, they did not consider a number of alternative features that have been proved to impact the performance of class-level bug prediction models, namely textual, code smell-related, and developer-based metrics [10, 58, 93]. We tackle these limitations by (1) estimating the models’ performance using data from subsequent releases (as done by more recent studies, which did it at a coarser granularity [104]), and by (2) adding a set of new alternative features to the considered method-level bug prediction model.

Our results show that—when evaluated on a release-by-release strategy—all the existing method-level bug prediction models present lower performance, close to that of a random classifier. As a consequence, even though we could replicate the reference work, a more realistic evaluation lead to negative results. Furthermore, all the alternative features we experiment with only marginally improve the performance, suggesting that method-level bug-prediction is still not a solved problem.

2. Background and Related Work

Research in the field of bug prediction is highly active [50, 56] and can be roughly divided in two sets: On the one hand, researchers focused on the characteristics relating to source code being more defect prone [102, 62, 87, 2, 3, 6, 23, 86, 89, 112]; on the other hand, researchers defined bug prediction techniques based on unsupervised [35, 80, 126] and supervised [18, 38, 59, 92, 128] approaches. More recently, the concept of just-in-time bug-prediction has been introduced—techniques with the purpose of recommending defective files as developers commit them [60, 110, 125, 97, 20, 21, 55].

The current paper presents a work that focuses on investigating how well supervised approaches can identify bug-prone methods. In this section we discuss the literature related to class-/method-level bug prediction and describe the role of textual information for software quality.

2.1. Class-level Bug-Prediction

The approaches in this category differ from each other mainly for the underlying prediction algorithm, e.g., Logistic Regression vs Random Forest, and for the considered features, e.g., product (e.g., lines of code) or process metrics (e.g., number of changes performed to a class).

Product metrics. Basili et al. [5] found that five CK metrics [27] can help one to determine defective classes and that Coupling Between Objects (CBO) is the most related to bugs. These results were re-confirmed in further studies [48, 61, 113]. Ohisson et al. [83] focused on design metrics (e.g., ‘number of nodes’) to identify bug-prone modules, revealing the applicability of such metrics for the identification of buggy modules. Nagappan and Ball exploited two static analysis tools to predict the pre-release bug density for Windows Server [77]. Nagappan et al. [78] experimented with code metrics for predicting buggy components across five Microsoft projects, finding that no single metric is the best across all projects. Zimmerman et al. [128] investigated complexity metrics for bug-prediction and reported a positive correlation between code complexity and bugs. Nikora et al. [81] showed that measurements of a system’s structural evolution (e.g., ‘number of executable statements’) can serve as bug-predictors. More recently, Dan et al. [31] reported an experience report of using product metrics and abstract representation of source code in practice, showing that it is possible to achieve good prediction accuracy when employing them within deep learning models.

Process metrics. Graves et al. [119] experimented with both product and process metrics for bug-prediction, finding that product metrics are poorer predictors for bugs. Moser et al. [76, 106] performed two comparative studies, which provided additional corroborating evidence on the superiority of process metrics in predicting buggy code components. Later on, D’Ambros et al. [34] performed an extensive comparison of bug-prediction approaches relying on both product and process metrics, finding that no technique works better in all contexts.

Despite the aforementioned promising results, a study by Shihab et al. [109] reported that developers consider class or module level bug-prediction too coarse-grained for being useful in practice. Also, a study by Lewis et al. [68] reported similar issues when trying defect prediction in practice at Google. This situation calls for the creation of methods able to provide a more fine-grained prediction (e.g., at method-level), re-evaluating and adapting what has been learned in the preceding work.

Alternative metrics. Despite product and process features have been the most widely used for bug prediction purposes, researchers have been also investigating the value of alternative metrics. In this category, several researchers exploited developer-related factors. For example, Hassan investigated a technique based on the entropy of developers’ code changes [53], finding that it has better performance than models based on changes to code components. Ostrand et al. [10, 85] proposed the use of the number of developers who modified a code component as a bug-proneness predictor: however, the performance of the resulting model was poorly improved with respect to existing models. Later on, Di Nucci et al. [37] defined a bug-prediction model based on a mixture of code, pro-
cess, and developer-based metrics outperforming the performance of existing models. As part of their experimentation, Di Nucci et al. also re-assessed the contribution given by the metric proposed by Ostrand et al. [10, 85], showing that in certain circumstances the number of developers may represent a relevant factor to characterize the bug-proneness of classes. Bird et al. [14] found that the addition of an information related to the code ownership of classes can make bug prediction models more accurate; these findings were later confirmed by other researchers [47, 103]. On a similar line of research, socio-technical factors have been also exploited for bug prediction: for instance, Posnett et al. [102] proposed two novel metrics based on the developer’s social-network that may be used as predictors of faults in production, while Bird et al. [13] studied how developers contribute to source code and found that lack of collaboration and coordination are associated with an increase of the number of bugs.

Other researchers focused on improving bug prediction capabilities using the information coming from code smells [43], i.e., sub-optimal design implementations applied by developers. Khomh et al. [62] and Palomba et al. [87] indeed reported that such smells have a strong, negative impact on the bug proneness of source code. Following these findings, Taba et al. [114] studied how the addition of variables characterizing the presence of 13 different types of code smells can improve the performance of bug prediction models built using standard product metrics: they reported an improvement close to 13% in terms of F-Measure. Later on, Palomba et al. [93] showed that the intensity of code smells, namely a measure of their severity, can further improve bug prediction capabilities with respect to the work of Taba et al. [114].

Finally, a less explored yet worth to discuss bug prediction angle concerns the usage of textual metrics. In the first place, the use of textual information has represented a promising and orthogonal dimension to improve software quality assessment [52, 71, 123]. For instance, textual information has already been used in several software engineering tasks or activities such as information retrieval [70, 71, 94], code smell detection [88, 91, 89], refactoring [7, 8, 9], and meaning extraction [96]. Perhaps more importantly, the addition of textual-related information has been proved to enhance the performance of bug prediction models. Marcus et al. [71] defined the Conceptual Cohesion of Classes (C3) and added it within a bug prediction model based on product metrics, finding that textual information can provide a boost of ≈23% in terms of F-Measure. Walid et al. [58] provided initial compelling evidence that a lack of coherence between code comments and corresponding source code (due to the missing update of code documentation) impacts the bug-proneness of code elements. Aman et al. [1] further explored the problem and found that certain types of code comments (e.g., those explaining functionalities implemented in a class) are associated with a higher bug-proneness of the code. Later on, Buse and Weimer [16] found that poor readability of source code contributes to the identification of buggy classes. These findings were also confirmed by Binkley et al. [12], who showed that a lower source code readability is often associated to an increase of the production code fault-proneness; When employed within predictive models, readability metrics provide an additional contribution that allow these models to perform ≈10% better than models built without using them.

Inspired by the results of these previous studies, in this work we aim at evaluating the effect of characterizing bug-prone methods considering alternative features, thus providing a wider overview of the performance achievable with method-level bug prediction.2

2.2. Method-level Bug-Prediction

While the seminal idea of lowering the granularity of bug prediction is to attribute to Menzies et al. [74] and Tosun et al. [120], the work by Giger et al. [46] was the first explicitly aimed at predicting bugs at method-level in object-oriented software systems. Giger et al. defined a set of product and process metrics to characterize a method and evaluated these metrics in three method-level bug prediction models, respectively based on: (i) product metrics, (ii) process metrics, and (iii) their combination. Giger et al. [46] found that both product and process metrics contribute to the identification of buggy methods and their combination achieves the best performance (i.e., F-Measure=86%). To produce the dataset used in their evaluation, Giger et al. took the following steps [46]: they (1) considered a large time frame in the history of 21 Java OSS systems, (2) focused on the methods present at the end of the time frame, (3) computed product metrics for each method at the end of the time frame, (4) computed process metrics (e.g., number of changes) for each method throughout the time frame, and (5) counted the number of bugs for each method throughout the time frame, relying on bug fixing commits. Finally, they used 10-fold cross-validation [64] to evaluate the three aforementioned models, considering the presence/absence of bug(s) in a method as the dependent (binary) variable. Similarly to the paper discussed above, Hata et al. [54] proposed a fine-grained prediction model in which they computed a number of historical metrics to predict the bug-proneness of Java methods. Their results reported that method-level predictions are more effective than file- and package-level ones when considering the effort required by developers to locate and debug a potential defect in source code.

In this work, we re-evaluate the paper by Giger et al. [46] using data from subsequent releases (i.e., a release-by-release validation), which better models a real-case scenario where a prediction model is updated as soon as new information is available.3 The choice of focusing on the

2This part is a novel contribution of this paper.

3This part was previously presented at an academic software engineering conference [97].
work of Giger et al. [46] rather than the one of Hata et al. [54] is motivated by the fact that Giger et al. experimented with both code and process metrics (as opposed to Hata et al. who only considered process metrics), thus giving us the opportunity of providing a wider overview of the performance of method-level defect prediction.

3. Research Goals and Context

In this section, we define both the research questions guiding our study and the context of our investigation.

3.1. Research Questions

The goal of the empirical study is to re-evaluate how bug prediction can be applied at method-level, with the purpose of understanding the performance of models built using different sets of features. We start our investigation by replicating the study conducted by Giger et al. [46] on a partially overlapping set of software systems (but considering different moments in time) to evaluate the generalizability of their findings. Thus, we ask:

RQ 1. How effective are existing method-level bug prediction approaches when tested on new systems/timespans?

While replicating the methodology proposed by Giger et al. [46], we detected some limitations concerning the validation approach: (1) it uses 10-fold cross-validation, which is at the risk of producing biased estimates in certain circumstances [118], (2) product metrics are considered only at the end of the time frame (while bugs are found within the time frame), and (3) the number of changes and the number of bugs were both considered in the same time frame (this time-insensitive validation strategy may have led to biased results). Thus, in the second part of our study we try to overcome the aforementioned limitations by re-evaluating the performance using data from subsequent releases. A release-by-release validation better models a real-case scenario where a prediction model is updated as soon as new information is available. Our expectation is that the performance is going to be weaker in this setting. This leads to our second research question:

RQ 2. How effective are existing method-level bug prediction models when validated with a release-by-release validation strategy?

A second limitation we identify is related to the independent variables exploited by Giger et al. [46]. While they performed an extensive analysis of product and process metrics, the role of other types of information—that have been shown to boost the performance of bug prediction models in the past [12, 58, 71]—was not assessed. In the context of our study, we assess the impact of three families of metrics such as: (1) textual features, whose aim is to capture the readability of the considered code as well as its alignment with code comments and their types; (2) code smells [43], which describe potential design flaws in source code; and (3) developer-related factors, that analyze properties related to the developers working on a system. Hence, we ask:

RQ 3. How effective are method-level bug prediction models built using alternative features?

3.2. Subject systems

The context of our work consists of 13 software systems whose characteristics are reported in Table 1. For each system, the table reports its size (in terms of LOCs) and how many developers contributed over the entire history, as well as the number of releases, methods, and buggy methods. In particular, we focus on systems implemented in Java (i.e., one of the most popular programming languages [39]), since both the metrics previously defined by Giger et al. [46] and the alternative features proposed in this study mainly target this programming language. In addition, we select projects whose source code and change history are publicly available (i.e., open-source software projects using a version control system) to enable the extraction of product, process, and alternative metrics.

Starting from the 81,327,803 open-source systems written in Java available at the time of the analysis on Github, we first filter out those having less than 1,000 commits and more than 5,000 methods: this filter gives us a total of 6,753,654 systems. Finally, we randomly select 13 of them. Compared to Giger et al. [46], we consider fewer, but larger systems, which are composed of a much larger number of methods (1.8M vs 112,058) and bugs (63,400 vs 23,762). This choice allows us to test the effectiveness of method-level bug prediction on software systems of a different scale.

4. RQ1. Replicating Method-Level Bug Prediction

Our first research question aims at replicating the study conducted by Giger et al. [46] on a different set of systems and time spans.

4.1. RQ1 - Research Method

To answer our first research question, we (i) build a method-level bug prediction model using the same features as Giger et al. [46] and (ii) evaluate its performance using the original evaluation strategy and applying the model to our projects. To this aim, we follow a set of methodological steps such as (i) the creation of an oracle reporting buggy methods in each of the projects considered, i.e., the dependent variable to predict, (ii) the definition of the independent variables, i.e., the metrics on which the model relies on, (iii) the assessment of the performance of different machine learning algorithms, and (iv) the definition of the validation methodology to test the performance of the models devised in the reference paper.

Extraction of Bug Data. For each system we need to detect the buggy methods contained at the end of the time frame, i.e., in the last release $R_{last}$, to do so we use a methodology in line with that followed by Giger et al. [46]. Given the tagged issues available in the issue tracking systems (i.e., Bugzilla or JIRA) of the subject systems, we use ReLINK [124] to identify links between issues and commits.5 Afterwords, we consider as buggy all the methods changed in the buggy commits detected by ReLINK and referring to the time period between the $R_{last-1}$ and $R_{last}$ (i.e., the ones introduced during the final time frame). We discarded test cases because tests may be modified with the production code without being implicated in a bug. Table 2 reports the release tags together with the number of files, methods, and defective methods used to answer RQ1.

</table>

- **Product Metrics**: Existing literature demonstrated how effective product metrics are in characterizing the extent to which a source code method is difficult to maintain, possibly indicating the presence of defects [5, 27, 83, 34]. Giger et al. [46] proposed the use of the metrics reported in Table 3. The features regard different method characteristics, e.g., number of parameters or McCabe’s cyclomatic complexity [72]. Although this may introduce a threat to the validity of our results, we had to re-implement all of the metrics due to the lack of available tools.

- **Process Metrics**: According to previous literature [106, 115], process features can complement the capabilities of product predictors for bug prediction. For this reason, Giger et al. [46] relied on the change-based metrics described in Table 4. These metrics characterize the life of source code methods (e.g., by considering how many statements were added over time or the number of developers that touched the method). As we did for product metrics, we had to...
reimplement the proposed process metrics defined at method-level by Giger et al. [46].

In line with Giger et al. [46], in the context of RQ1, we build three different method-level bug prediction models relying on (i) only product metrics, (ii) only process metrics, and (iii) both product and process metrics.

**Preprocessing The Training Data.** Once obtained the subject dataset, we tackle two common problems that may affect machine learning algorithms: (i) data imbalance [26] and (ii) multi-collinearity [82]. We address the former problem by applying the Random Over-Sampling algorithm [25] implemented as a supervised filter in the Weka toolkit. The filter re-weights the instances in the dataset to give them the same total weight for each class maintaining unchanged the total sum of weights across all instances. We address the second problem by filtering out the unwanted features. Specifically, we apply the Correlation-based Feature Selection [49] algorithm implemented as a filter in the Weka toolkit. It computes the correlation between each pair of features and, if this is higher than 0.7, removes one of them by considering their individual predictive power.

**Machine Learner.** Once the training data is preprocessed, we need to select a classifier that best leverages the independent variables to predict buggy methods [44]. To this aim, we investigate the four classifiers used by Giger et al. [46]: Random Forest, Support Vector Machine, Bayesian Network, and J48. Afterwards, we compare the different classification algorithms using the validation strategy and metrics described later.

**Evaluation Strategy.** The final step to answer RQ1 is the validation of the prediction models. As done in the reference work, we adopt the 10-fold cross-validation strategy [64, 116]. This strategy randomly partitions the original set of data into 10 equal sized subset. Of the 10 subsets, one is retained as test set, while the remaining nine are used as training set. This validation is then repeated 10 times, switching on which subset the model is tested.

**Evaluation Metrics.** Once we had run the experimented models over the considered systems, we measure their performance using the same metrics proposed by Giger et al. [46] to allow for comparison: precision and recall [4]. Precision is defined as

\[
\text{precision} = \frac{|TP|}{|TP\cup FP|} \tag{1}
\]

where \(TP\) (True Positives) are methods that are correctly classified as buggy by the prediction model and \(FP\) (False Positives) are methods that are wrongly classified as buggy. Recall is defined as

\[
\text{recall} = \frac{|TP|}{|TP\cup FN|} \tag{2}
\]

where \(FN\) (False Negatives) are buggy methods misclassified as non-buggy by the model. We also compute F-Measure [4], which combines precision and recall:

\[
F\text{- Measure} = 2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}} \tag{3}
\]

In addition to the aforementioned metrics, we also compute the Area Under the Receiver Operation Characteristic curve (AUC-ROC) [51]. In fact, the classification chosen by the machine learning algorithms is based on a threshold (e.g., all the method whose predicted value is above the threshold 0.5 are classified as buggy), which can greatly affect the overall results [118]; precision and recall alone are not able to capture this aspect. ROC plots the true positive rates against the false positive rates for all possible thresholds between 0 and 1; the diagonal represents the expected performance of a random classifier. AUC computes the area below the ROC and allows us to have a comprehensive measure for comparing different ROCs: An area of 1 represents a perfect classifier (all the defective methods are recognized without any error), whereas for a random classifier an area close 0.5 is expected (since the ROC for a random classifier tends to the diagonal).

4.2. RQ1 - Results

Table 5 reports the median values for precision, recall, F-measure, and AUC-ROC achieved by models based on (i) only product, (ii) only process, and (iii) both product and process features when using different classifiers. To ease the comparison between our replication (‘O’ in Table 5) and the work of Giger et al. [46], in the table we also report the results achieved by the original work (‘o’ in Table 5). Overall, from this first analysis we can claim that the obtained results are in line with those by Giger et al. [46], yet 10 percentage points lower on average.

The model based on product metrics achieves the lowest results. For instance, the overall precision is 0.71, meaning that a software engineer using this model has to needlessly analyze almost 29% of the recommendations it outputs. This result is in line with the findings provided by Giger et al., who showed that the model only trained on product metrics offers generally lower performance.

Secondly, our results confirm that process metrics are stronger indicator of bug-proneness of source code methods (overall F-Measure=0.80). This finding is in line with the previous results achieved by the research community.
that report the superiority of process metrics with respect to product ones [104, 106]. Our results also confirm another finding by Giger et al. [46]: The combination of product and process metrics does not improve dramatically the prediction capabilities: Results are—at most—two points percentage higher than the model with process metrics only. This is surprising, because we expected that the use of these orthogonal predictors would improve the overall performance.

With respect to the different classifiers we experimented, Support Vector Machines gives the worst results; likely, this is due to the extreme sensitivity of the classifier to the configuration [29]. Future studies could be setup and conducted to investigate the impact of the configuration on SVM for method-level bug prediction. Other classifiers provide more stable results. Random Forest and J48 obtain the best prediction accuracy considering all the evaluation metrics. The differences are particularly evident when considering the AUC-ROC values, which are 36% and 29% higher than VSM, respectively. Our results confirm what was reported by Giger et al. on the capabilities of Random Forest and, more in general, on the performance of this classifier for bug prediction [38, 69].

We compared the AUC-ROC values of the experimented models using the Scott-Knott Effect Size Difference (ESD) test [117]. As a result, process-based models built using Random Forest and J48 are statistically better than product-based ones, while they work similarly to the combined ones.

\[\text{ESD} = \text{Product} - \text{Process} \]

**Result 1:** Our results, evaluated with the same strategy but on a different set of systems/timespans, confirm the findings by Giger et al. [46]: Method-level bug prediction models based on process metrics outperform those based on product metrics. Our results are 10 percentage points lower than those of Giger et al., yet far better than random. Combining predictors with different nature improves the prediction only marginally.

5. Limitations Of The Existing Approach

By replicating the work by Giger et al. [46], we could identify two possible major points for improvement: the evaluation strategy and the set of features employed.

Reflecting on the evaluation strategy. Figure 1 shows an exemplification of the history of a system and how the training and testing are done in the approach by Giger et al. (named ‘10-fold overall evaluation’ in the figure and depicted using red lines and text) and in the one we propose in this work (named ‘release-by-release’ and depicted in blue).

The system in Figure 1 has four methods (i.e., \(M_a, M_b, M_c, M_d\)) that were changed several times throughout the history of the system. The changes sometimes were related to a bug (i.e., the method was involved in a bug fix; purple dot), sometimes not (i.e., green dot). For example method \(M_a\) was changed four times, two of which involving a bug fix. This system had at least three releases (i.e., \(R_x\) throughout \(R_{x+1}\)).

The approach applied by Giger et al. collects all the available information until the ‘data collection point’, then marks a method as ‘buggy’ whenever the method was involved in a bug fix (i.e., it was buggy before the bugfix) in the entire history of the system. Then, each method would be considered as an instance to classify, where the independent variable is whether the method was marked as ‘buggy’ or not. In this case, the validation would be done vertically: 10-fold cross validation ensures that the classifier is trained on a subset of methods (e.g., \(M_a, M_b, M_c\).
Figure 1: Training and testing strategies for method-level bug prediction.

Figure 1) that is different from that used for the testing (e.g., $M_d$). The limitation of this approach is that it uses dependent variables (such as most of the process metrics, including ‘number of changes’) (1) whose value could not be known at prediction time in a real-world scenario (i.e., one would try to predict bugs that still have to occur, not that have already happened) and that (2) seem to be highly correlated to the independent variable (for each bug fix there has to be at least one change). Moreover, there are moments in which the methods were not buggy, but if they have been buggy at least once in the lifetime of the system, they are considered as buggy. Although reasonable for an initial validation, the approach followed by Giger et al. may lead to unreliable results.

To try to avoid unreliable results, we propose a release-by-release strategy, similar to one adopted by Kpodjedo et al. [65]. We train and test “horizontally” instead of “vertically”: We assume the stakeholder interested in the prediction to be in the moment of a release (e.g., $R_{x+1}$ in Figure 1) and we train on all the information available from the previous release to this moment (e.g., from $R_x$); in this case the dependent variable is whether a method has been buggy during the considered release. Then, we consider the next release (e.g., $R_{x+2}$) and try to predict which methods will be buggy in the course of the development of this release. We do not consider any information available from the current release to the next, because this would not be available in real life. With this strategy we are going to answer RQ3.

An addition to the release-by-release strategy would be to consider the SZZ algorithm [111] and consider as buggy only the methods in which a bug was introduced before the release (regardless of when the fix happened). We decided not to follow this path for three reasons: (1) SZZ could give information that is not available at prediction time (e.g., when the bug fix happens after the considered release, but the bug inducing commit happens before the release), (2) SZZ has been proven to be not reliable [30], and (3) we want to reduce at a minimum the differences from the work of Giger et al. we are replicating, so that the obtained results are not due to unconsidered causes.

Reflecting on the independent variables. As shown in previous work [104, 63], the choice of the features to employ when classifying defective components is key for the performance of bug prediction. In the work by Giger et al. [46], the authors investigated a variety of product and process metrics: while the experimental setting already dealt with the differences among these two sets of features, it is worthwhile to consider extensions to it.

Looking at the existing literature, textual features have been shown to be valuable for both software quality assessment in general and class-level bug prediction in particular. Thus, we propose to investigate the extent to which features regarding code readability and alignment of comments can improve existing bug prediction models at method level. In RQ3, therefore, we define a set of features based on previous literature and test whether (i) a model solely based on those features perform better than the existing ones and (ii) their addition to a combined model (which also features process and product metrics) can give lead to improved performance.
6. RQ2 - Re-evaluating Method-Level Prediction

We seek to evaluate the performance of method-level bug prediction models in a more realistic setting.

6.1. RQ2 - Methodology

To answer RQ2, we need to (i) extract all the releases of the considered projects, (ii) identify the buggy methods in each of the releases, and (iii) build the three bug prediction models used for RQ1.

Extracting the Major Releases. The first step to test the performance of method-level bug prediction models is the identification of the major releases in the considered systems. To this purpose, we automatically extract the releases from the list of releases declared on the GitHub repository of the subject systems. To discriminate a major release from the others, we rely on a heuristic based on naming conventions: If the version name ends with the patterns 0 or 0.0 (e.g., versions 3.0 or 3.0.0), then we define it as a major release.\(^\text{13}\)

Extraction of Bug Data. Differently from what we have done in RQ1, in this research question we need to extract the data about the bugs for all the considered releases. For each release pair \(r_{x-1}\) and \(r_x\), we (i) run ReLink and (ii) consider as buggy all the methods actually changed in the buggy commits detected by ReLink and referring to the time frame between \(r_{x-1}\) and \(r_x\). We removed the test cases, as in RQ1. Table 6 summarizes the distribution of buggy methods considering every inspected release for each project.

Bug Prediction Models: Setup. As done for RQ1, we test the performance of three bug prediction models, i.e., the ones relying on (i) product metrics only, (ii) process metrics only, and (ii) both product and process metrics, built using the same set of machine learning approaches (i.e., Random Forest, Support Vector Machine, Bayesian Network, and J48). The training data is pre-processed to avoid (i) data unbalance and (ii) multicollinearity, by using the techniques previously exploited (i.e., Random Over-Sampling algorithm [25] and Correlation-based Feature Selection [49], respectively).

Table 6: Distribution of defective methods over the releases.

6.2. RQ2 - Results

Table 7 reports the median precision, recall, F-measure, and AUC-ROC achieved by models based on (i) only product, (ii) only process, and (iii) both product and process metrics when using different classifiers and the release-by-release strategy.\(^\text{14}\)

The performance achieved by all the prediction models experimented is substantially lower than those found for RQ1. We observe a lower variance in the results, for each of the subject systems in our dataset.

In this evaluation scenario, code metrics achieve better performance than process metrics. This is in contrast with past literature reporting the superiority of process metrics for bug prediction [104, 106]. We hypothesize that this result may be caused both by the different granularity of the experimented models and by the different validation strategy. In particular, while the historical information computed at class-level could better characterize the complexity of the development process followed by developers while implementing changes in an entire class [53], it is reasonable to think that the bugginess of source code methods may be better expressed by the methods’ current code quality. An additional possible cause that refutes the observation of previous studies [104, 106] comes from the irregular distribution of the length of the time frames for the considered releases. In our analyzed projects, these intervals stretch from a few months to a couple of years and the distribution of the releases is strictly correlated to the needs and the approach adopted by developers in a given historical moment. The higher prediction capabilities of code metrics are confirmed also when looking at other indicators, i.e., precision, recall, AUC-ROC. Moreover, this result holds for all the classifiers considered.

Finally, the performance of the different classifiers has also lower variance. To some extent, this result confirms previous findings in the field [45, 95] showing that different classifiers achieve similar performance. Alternatively, this similarity in results and the low performance may indicate that no machine learning algorithm detects a valid signal.

\(^{13}\)We manually verified the performance of this heuristic on one of the subject systems: We verified that all the major releases of LUCENE-SOLR were correctly caught, thus quantifying the actual performance of this approach.

\(^{14}\)Our appendix provides detailed reports [98].
from the considered metrics. This result potentially highlights the possibility to further study the orthogonality of classifiers for method-level bug prediction with the aim of exploiting ensemble methodologies [38, 69].

**Result 2:** Method-level bug prediction models resulted in much lower performance (up to 20 points percentage less) in terms of AUC-ROC and similar precision when evaluated with the more practical release-by-release evaluation strategy. The achieved AUC-ROC scores achieved by all the models, regardless of the machine learning approach, are close to the results of a random classification.

7. **RQ 3. Evaluating Alternative Metrics**

Our RQ 3 seeks to evaluate the potential of alternative metrics for method-level bug prediction.

7.1. **RQ 3 - Methodology**

We define a set of metrics based on textual aspects of source code as well as code smells, and developer-related factors, which we include in the method-level bug prediction models experimented in our previous research questions. In the following, we first describe the metrics and the rationale for their choice, and then we detail the model definition and evaluation process.

**Textual Metrics.** As summarized in Section 2, previous work [1, 12, 16, 58] highlighted that textual aspects of source code could impact its bug proneness and be useful when considered within bug prediction models. Thus, we first challenge these findings and explore the role of textual features when applied to method-level bug prediction. Table 8 lists the considered metrics. We include:

**Code Readability.** Based on the findings by Buse and Weimer [16] and Binkley et al. [12], we compute a measure of readability of source code. We directly employ the tool proposed in [16]: This outputs an index, which is a decimal score ranging between 0 and 1, where 0 represents unreadable code and 1 refers to easily readable code. This tool relies on a readability model composed of 19 metrics (including line length, number and length of identifiers, number of a predefined list of characters, branches, loops). To compute it, we rely on the publicly available version of the tool provided by the authors.¹⁵

Code readability is not code complexity, which we already defined in other metrics previously.

**Table 8:** List of the considered method-level textual metrics.

<table>
<thead>
<tr>
<th>Metric name</th>
<th>Description (applies to method level)</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Readability</strong></td>
<td>Source code readability index [16]</td>
</tr>
<tr>
<td><strong>Textual Coherence</strong></td>
<td>Measure of the textual coherence between source and code comments [58]</td>
</tr>
<tr>
<td><strong>Purpose</strong></td>
<td># of code comments used to describe the functionality of linked source code</td>
</tr>
<tr>
<td><strong>Notice</strong></td>
<td># of code comments related to the description of warning, alerts, or messages</td>
</tr>
<tr>
<td><strong>Development</strong></td>
<td># of code comments covers the topics related to the ongoing and future development</td>
</tr>
<tr>
<td><strong>Style&amp;IDE</strong></td>
<td># of code comments used to logically separate the code or provide special services</td>
</tr>
<tr>
<td><strong>Metadata</strong></td>
<td># of code comments used to classify comments that define meta-information about the code</td>
</tr>
<tr>
<td><strong>Other</strong></td>
<td># of code comments that do not fit into the previously defined categories</td>
</tr>
</tbody>
</table>

**Textual Coherence.** Based on the findings reported by Walid et al. [58], we measure the textual coherence, *i.e.*, the extent to which comment and source code of a method are aligned. To compute it, we first normalize comments and source code using a standard Information Retrieval (IR) process [4].¹⁶ Then, we apply the Vector Space Model (VSM) [4] and measure the textual similarity between comments and source code (*i.e.*, the vectors of VSM) using the cosine distance.

**Comment Classification.** Based on the findings by Aman et al. [1], who reported that different comments types are associated to different bug proneness, we classify source code comments exploiting the model proposed by Pascarella and Bacchelli [96]: It analyzes the text contained in a comment and classifies its semantic. Specifically, Pascarella and Bacchelli defined a hierarchical taxonomy with two levels: the first coarse-grained contains 6 categories, while the second fine-grained contains 16 sub-categories. In our study, we define 6 new categories.

¹⁵**URL:** http://www.arrestedcomputing.com/readability.

¹⁶In detail, we (i) separate composed identifiers, (ii) lower case the extracted words, (iii) remove special characters, programming keywords, and common English stop words, and (iv) stem words to their original roots via Porter’s stemmer [101].
method-level textual metrics based on the first level, as described by the last six rows in Table 8.

**Code smells.** These are poor design or implementation choices introduced by developers when maintaining and/or evolving software systems [43, 121]. The addition of the information on the design quality of classes into existing bug prediction models has been proved to improve bug identification capabilities [93, 114]. The contribution of measures of code smell severity appeared to be particularly useful in class-level bug prediction [93]. Following these findings, in the context of our work, we first identify code smell types that affect methods and then compute their intensity. We focus on:

**Long Method.** This smell refers to methods implementing more than one functionalities and is generally detected by considering its size [43]. Methods affected by this smell are poorly cohesive and possibly impact their understandability, change- and defect-proneness [87].

**Long Parameter List.** This smell refers to methods having a long list of parameters. Instances of this smell can lower the maintainability of methods and possibly indicate that the method is poorly cohesive [43].

**Message Chains.** This smell occurs when a client requests an object; this requires yet another one, and so on, thus creating a long concatenation of method calls [43]. This smell has been associated to a higher defect-proneness of the affected methods [32, 87].

The rationale behind the selection of these code smell types is twofold. In the first place, these have been reported to occur in software projects [87]. Perhaps more importantly, they influence the bug-proneness of the affected methods [87, 32], thus perfectly fitting the goal of our paper.

To detect them we rely on DECOR [75], a method to define code smell detection rules using a Domain-Specific Language. The approach uses a set of rules, called “rule cards”, which describe the intrinsic characteristics that a method should have to be affected by a certain code smell type. In the case of *Long Method*, DECOR identifies it by considering the number of lines of code of a method: If this is higher than 80, then a code smell is detected. As for *Long Parameter List*, it considers a method affected by this smell if it has more than three parameters. Finally, *Message Chains* instances are detected if a method contains a statement in which more than three method calls are performed.

According to several empirical studies [88, 89, 100], the accuracy of DECOR is relatively high both in terms of precision and recall, with typical values of F-Measure around 75%. This makes the detector more accurate than other available tools [41] and, therefore, suitable for our study.

Once detected code smell instances, we compute their intensity. We follow a similar approach as previous work [89, 90]: as DECOR classifies a method as smelly if a specific condition is satisfied, for instance, if its lines of code > 80, we can say that the higher the distance between the actual code metric value and the fixed threshold, the higher the intensity of the smell. We use this approach to compute the intensity of all the three smells considered.

**Developer-related factors.** Aspects capturing how developers work on source code and what is the change process they apply when performing software maintenance and evolution activities have been often successfully applied in bug prediction as they showed a great potential for improving predictive models [14, 24, 37, 53, 85].

These previous findings lead us to consider how developer-related factors work when employed in the context of method-level bug prediction. In particular, we focus on three orthogonal aspects such as:

**Number of developers.** In the first place, for each method of the considered dataset, we compute how many distinct developers worked on it over the history of the project. The contribution of this metric to bug prediction capabilities was firstly assessed by Ostrand et al. [10, 85], who reported that individual developer’s data provides a limited boost to bug prediction models; Nevertheless, Di Nucci et al. [37] performed a larger empirical evaluation of the value of this metric, showing that it can improve the performance of these models by up to 10%. This is the reason why we seek to understand its value at a finer-level. We compute the metric by (i) mining all commits in the change history that changed a method and (ii) counting the number of developers who made changes to it. To distinguish different developers, we consider the e-mail address they left on GITHUB—we are aware that this computation may be imprecise in cases where a developer uses multiple e-mails when working on the project, however there is no practical way to solve this problem.

**Code ownership.** According to Bird et al. [14], developers having a higher experience on the source code they touch are less prone to introduce bugs. The authors assessed this relation by computing the code ownership of classes and measuring its impact on the performance of bug prediction models, finding that models including this metric have an accuracy that is 24% higher than those not including it as a feature. In our work, we compute code ownership at method-level by following the same approach of Bird et al. [14]: given a method m, we compute the ratio of number of commits that a contributor c has made on m with respect to the total number of commits made by c. Once computed the metric for all developers who contributed to m, we assign to the method the maximum ownership computed.
Entropy of code changes. Finally, we take into account the way developers make changes in a system and compute the entropy of changes originally defined by Hassan [53] for class-level bug prediction. This metric has been shown to strongly impact on the performance of predictive maintenance models [22, 53]. Following the algorithm of Hassan [53], we first identify all commits which modified a method \( m \) and then run a pattern-based technique that can detect the so-called feature-introduction modifications, namely changes applied to introduce new or enhancing existing features. Afterwards, the entropy of changes on \( m \) is computed exploiting the concept of Shannon entropy [108] as in the following equation:

\[
\text{entropy}(m, \alpha) = -(p_{m,\alpha} \cdot \log_2 p_{m,\alpha}) \tag{4}
\]

where \( p_{m,\alpha} \) indicates the probability that \( m \) was changed received feature introduction modifications over its change history. This probability is computed considering the fraction between the number of feature introduction modifications applied on \( m \) in the change history over the total number of feature introduction modifications applied by developers.

It is important to remark that other alternative metrics have been proposed by researchers in the bug prediction field, like for instance socio-technical [37, 102] or code coverage features [15]. Being aware of those alternative metrics, we decided to exclude them from our study as they cannot be easily computed at method-level. For instance, let consider the case of socio-technical [19]: this measures how much the organizational structure of a development community reflects the actual technical organization among developers. While the metric has been defined in terms of how much the developers’ social network matches the modularization of packages, no definition is available with respect to the socio-technical congruence between developers’ social network and division of methods among classes. Thus, we preferred to be conservative and not define any novel metric that would have deserved a separate validation before being used in our context. Rather, we relied on metrics that can be directly computed at method-level, e.g., the considered code smells are all directly computable at method-level.

Model Definition and Data Analysis. To test the contribution given by the considered families of features, we build five classes of method-level bug prediction models on the basis of those defined for RQ1. Our methodology is inspired by the one of Bird et al. [14]: starting from the baseline one, namely the product + process one defined by Giger et al. [46], we progressively fed up the model with additional features, so that we can measure the contribution given by each family of features to the capabilities of method-level bug prediction (if any). Hence, we build models relying on (i) product + process + textual features, (ii) product + process + textual + code smell-related features, and (iii) product + process + textual + code smell-related + developer-related features. Furthermore, we also build models relying on the various families of features independently so that we can assess the independent value of each of them for method-level bug prediction.

As done in the context of the previous research questions, we apply the RANDOM OVER-SAMPLING and Correlation-based Feature Selection [49] algorithms to deal with data balancing and multicollinearity. The performance of all experimented method-level bug prediction models are evaluated using the same validation strategy (i.e., release-by-release) and evaluation metrics (i.e., precision, recall, F-Measure, and AUC-ROC) used in the context of the previous research question. We also conduct a statistical comparison of the performance of the prediction models considered. The Mann-Whitney test [28] is not recommended in the case of comparisons of multiple models over multiple datasets, since the performance of a specific model might vary between two datasets [36]. Thus, we compared the AUC-ROC values of the experimented models over the different systems using the Scott-Knott Effect Size Difference (ESD) test [117].

7.2. RQ3 - Results

Figures 2 and 3 show the distribution of F-Measure and AUC-ROC, respectively, achieved by the prediction models built progressively using the various families of features considered in our study. We also report on the performance achieved by the models only relying on individual sets of features. Consistently with the methodology adopted for the first research question, we analyze how their performance varies when considering different classifiers (i.e., Simple Logistic, Logistic, Multilayer Perceptron, Random Forest, J48, Decision Table, and Naive Bayes). However, we limit the discussion of the results to Random Forest because it was the classifier providing slightly better performance (see Table 5).18

When looking at the figures, we can see that the models built using individual sets of features have poor performance: for instance, the AUC-ROC of the only textual model is close to 53%, which indicates that it is just slightly better than a random classifier. A similar discussion can be drawn for the other individual models, thus confirming that taking those features alone does not give advantages when it comes to the prediction of defective methods. These results confirm what has been previously reported in the literature on the importance of combining multiple features to boost the performance of bug prediction models [5, 37, 104].

Turning the attention to the combined models, we notice that the progressive addition of metrics only gives marginal contribution to the overall classification accuracy. Specifically, the inclusion of textual metrics into a model

\footnote{A complete overview of the results achieved when using other classifiers is available in our appendix [98].}
containing product and process metrics allows the model to have 4% and 5% more F-Measure and AUC-ROC. In the first place, this indicates that these metrics provide a limited amount of additional information to predict future bugs. At the same time, our findings represent a negative result with respect to the findings reported by all prior studies that we exploited to derive the textual features [1, 12, 16, 58]; indeed, we could not find any textual measure able to significantly increase the performance of the experimented prediction models.

The discussion is similar when considering the addition of code smell-related information. According to previous findings in the field [93, 114], including a measure of code smell severity within models relying on a combination of process and product metrics provides an increase of ≈15% in terms of F-Measure. Unfortunately, this is not the case when lowering the granularity of the predictions. In our case, indeed, the F-Measure of the product + process + textual + code smell-related model is even lower than the one not including any smell-related information (-2%). This may indicate that code smells computed at method-level have a limited predictive power when compared to class-level code smells. Thus, our findings are again negative with respect to previous work [93, 114]. Perhaps more importantly, we could not confirm the results of D’Ambros et al. [32], in which the authors reported that one of the considered smells, i.e., Message Chains, is the one that mostly affects the bug-proneness of source code methods.

As for the developer-related factors (named All metrics in Figures 2 and 3), their inclusion provides an increase of 4% with respect to the second best performing model (the product + process + textual one). So, also in this case, we claim that the contribution is marginal and that we could not confirm the role of developer-related factors for bug prediction when the granularity is that of methods.

The results discussed so far are all statistically significant. According to the ranking of the performance provided by the Scott-Knott ESD test [117], there is no model performing statistically better than the others, thus indicating that the addition of alternative metrics does not boost the performance of bug prediction.19

To conclude the discussion, based on the findings discussed so far we argue that the research on method-level bug prediction still needs notable steps to do for better supporting developers. Our paper provides initial compelling evidence of the need of novel, specific metrics able

19Detailed statistical results are reported in our appendix [98].
to capture method-level information that actually relate to the bug-proneness of methods.

**Result 3:** The addition of alternative features based on textual, code smells, and developer-related factors improves the performance of the existing models only marginally, if at all.

8. Threats to Validity

We describe the factors that can affect the validity of our empirical results.

**Threats to Construct Validity.** A first factor influencing the relationship between theory and observation is related to the dataset exploited. In our study, we relied on the same methodology previously adopted by Giger et al. [46] to build our own repository of buggy methods, i.e., we first retrieved bug-fixing commits using the textual-based technique proposed by Fisher et al. [42] and then considered as buggy the methods changed in that commits. While we cannot exclude possible imprecision and/or incompleteness of the data used in this study, we have re-evaluated the performance of the tool by Fisher et al. in our context finding that it could detect buggy commits with a precision of 84% correctly. Still in this category, we re-implemented the product and process metrics used to build the experimented models. This was due to the lack of a publicly available tool. When re-implementing such metrics we faithfully followed the descriptions provided by Giger et al. [46]. As for the alternative metrics, instead, we used available tools whenever possible (e.g., in the case of the comment classification [96] or when detecting method-level code smells [75]). To enable and stimulate the replicability of our study, we made all tools and scripts exploited publicly available in our online appendix [98]. As for the selection of the classifier to use when building the bug prediction model, we tested the performance of different classifiers, finding RANDOM FOREST to be the one providing the best performance. All the tested classifiers use the default parameters, since finding the best configuration for all of them would have been too expensive [11]. Future work can be devised to investigate the impact of parameters’ configuration on our findings.

**Threats to Conclusion Validity.** A first point of discussion regards the data pre-processing techniques adopted before the construction of the experimented bug prediction models. To ensure that the results would not have been biased by confounding effects such as data imbalance [26] or multi-collinearity [40], we adopted formal procedures aimed at (i) over-sampling the training sets [26] and (ii) removing non-relevant independent variables through feature selection [49]. As for the evaluation of the models, we complemented the results concerning the F-measure by relying on a threshold-independent metric such as the AUC-ROC. Furthermore, we supported our findings with an appropriate statistical test like the Scott-Knott ESD one [117].

**Threats to External Validity.** This category refers to the generalizability of our findings. While in the context of this work we analyzed software projects having different size and scope, we limited our focus to Java systems because some of the tools exploited to compute the considered metrics only work for this programming language (e.g., certain code smells have been only defined for Java [43]). Thus, we cannot claim generalizability concerning systems written in different languages as well as to projects belonging to industrial environments. Similarly, we considered a subset of the available metrics in each of the five families of features considered: in particular, we limited ourselves to the analysis of the metrics which previous works have analyzed, while we cannot exclude that different results could be achieved when considering different metrics (e.g., other method-level code smell types).

9. Conclusion

We investigated (i) the performance of different types of method-level bug prediction models when applied in a real-case scenario and (ii) the contribution given by textual features to existing bug prediction models. The main contributions made by our study are:

1. A re-evaluation on different systems/timespans of previously defined method-level bug prediction models. The results confirm previous findings in the field [46].

2. An empirical analysis of how the performance of existing method-level bug prediction models change when applied to a more realistic, release-by-release scenario. Our results provide evidence that current method-level bug prediction models do not dramatically outperform a random classifier; hence we reveal the need for further research in this area.

3. An empirical analysis of whether the performance of existing method-level bug prediction models can be improved by considering a set of 8 textual features. Our results reveal that the overall prediction capabilities lead to negligible improvements.

4. An online appendix [98] that reports the dataset and all the additional analyses performed in the work described in this paper.

Based on the results achieved so far, our future agenda includes (i) the replication of our study on a broader set of systems also considering ensemble methods [38, 69], (ii) the investigation of novel metrics to properly work for method-level bug prediction, and (iii) an *in-vivo* analysis of the capabilities of method-level bug prediction models, involving practitioners during their daily activities [66].
Acknowledgment

A. Bacchelli and F. Palomba gratefully acknowledge the support of the Swiss National Science Foundation through the SNF Projects No. PP00P2_170529 and No. PZ00P2_186090. This project has received funding from the European Union’s H2020 programme under the Marie Skłodowska-Curie grant agreement No 642954. The authors would like to thank the anonymous reviewers for the detailed and constructive comments on the preliminary version of this paper, which were instrumental to improving the quality of our work.
